

PROGRAM-DIRECTED CACHE PREFETCHING FOR MEDIA PROCESSORS

Field of the Invention

5 The present invention is generally directed to a method and system for prefetching consecutive data from memory, and more specifically, to prefetching consecutive data in response to hints included in programmed instructions.

Background of the Invention

10 Accessing computer memory for image and video processing functions imposes different requirements than accessing computer memory for carrying out general-purpose computing functions. In particular, many image/video processing functions are characterized by high *spatial* locality, meaning that the functions require access to pieces of data that are stored in close proximity to each other within memory. Typically, image data are stored in consecutive blocks of memory, and image functions, such as frame averaging and two-dimensional transposition, 15 generally require sequential access to the consecutive blocks of data. However, image/video processing functions characteristically have very little *temporal* locality, meaning that these functions typically don't need to reuse the same pieces of data within a short period of time. For example, functions such as frame averaging and two-dimensional transposition generally do not reuse the same blocks of data within a 20 short period of time.

Cache memories are well suited to temporarily store data for repeated access by a processor. Thus, cache memories are best employed when functions are executed that have sufficient temporal locality, because the data stored in the cache must be reused often in a relatively short time. However, caches are not well suited 25 for functions having primarily spatial locality. The ability of caches to exploit spatial locality is limited due to the relatively small size of cache lines, where a cache line is the smallest unit of memory that can be transferred between main memory and the cache. (Cache lines are also sometimes referred to as cache blocks.)

Many media processors try to overcome the limitations of caches by replacing 30 or supplementing them with direct memory access (DMA) controllers. Double

10056247-012402

buffering has become a popular programming technique when utilizing DMA controllers and takes advantage of the static and simple memory references in most image/video computing functions. With double buffering, the DMA controller transfers data to an on-chip buffer while the processor uses data stored in another on-chip buffer as its input. The roles of the two buffers are switched when the DMA controller and the processor are finished with their respective buffers.

Double buffering overlaps computation and memory transfers. This overlap hides memory latency very effectively. In addition, the memory bandwidth obtained is typically higher with DMA transfers than those obtained when fetching data from cache lines. There are two reasons for this. First, most modern main memory designs enable the address and data phases to be decoupled, so that addressing and data access periods can be overlapped. An example of this type of memory is RAMBUS™ dynamic random access memory (RDRAM). These main memories typically operate most efficiently when the supply of read addresses is uninterrupted and pipelined, which is possible with DMA data transfers. A continuous supply of addresses is more difficult to guarantee when using a cache, because a cache miss only results in a few words of data being loaded from main memory. In fact, a continuous supply of addresses is impossible unless the cache is non-blocking, meaning that the processor is not blocked (stalled) from continuing to execute instructions that access data in the cache during a cache miss. In double buffering, a block of data is typically large enough that the DMA controller will fetch a longer portion of a dynamic random access memory (DRAM) page than would be fetched during a cache miss. Since DRAMs are most efficient when accessing data within a page, double buffering also improves the data transfer bandwidth.

The use of double buffering enables computation-bound functions to minimize memory stalls, since it effectively hides the memory latency behind continued computing time. For memory-bound functions, efficient bandwidth utilization directly translates into better performance, because execution time is highly correlated with the memory bandwidth obtained.

The disadvantage of using DMA controllers for double buffering is that they make programming significantly more difficult. A DMA controller must be programmed separately from the main data processing. The DMA controller must also be properly synchronized to the program running on functional units. The programmer must keep track of where the data are stored and explicitly perform transfers between on-chip and off-chip memories. Current compiler technologies are unable to simplify most of these tasks. Thus, substantial programming effort

20121010 012402

expended in developing an image computing function is directed to establishing correct DMA data transfers.

It would be desirable to mimic the efficient memory addressing characteristics of functions running on a DMA controller to ensure that memory bandwidth utilization is high, while avoiding the need for difficult and time-consuming DMA programming. It would also be desirable to prefetch blocks of data larger than a cache line sufficiently early to avoid cache misses.

A particular concern with prefetching large blocks of memory is that a misprediction of the data that are needed will result in a large amount of useless data being transferred to the processor, since a prefetch is useful only when the prefetched data are employed by the processor before the data are replaced. High prefetching accuracy is therefore needed to avoid useless prefetches. Achieving a high accuracy in this task by using suitable hardware would require significant on-chip space, and it might take a significant amount of time for the hardware to collect the necessary information, such as memory addresses, from run-time information. Any delay in this decision-making process will incur costly cache misses early in the execution.

For these reasons, it would be desirable to use compile-time information to aid in prefetching. Preferably, such compile-time information would be determined indirectly from instructions (hints) provided by a programmer or compiler. For example, hints provided by the programmer or compiler could identify the region of data and a general direction in which to prefetch the data. This concept of providing programmed hints is referred to herein as program-directed prefetching (PDP). Although PDP requires the programmer's active role in creating the hints, the programming effort can be significantly reduced since the programmer does not have to deal with the complicated data transfer synchronization problem. Furthermore, since no DMA programming interface, which is architecture dependent, would be required, the portability of functions would be improved by providing a cache prefetcher.

Summary of the Invention

The present invention is directed to a method for prefetching data from a prefetch region of memory, based on a hint included in program instructions and other compile-time information that indicates the bounds of the prefetch region, a size of a prefetch block of data, and a location of the prefetch block of data. Rather than requiring a programmer or DMA controller to identify and control prefetch blocks of data, a reference address of a program instruction provides an indirect hint as to where to prefetch the data. The program instruction is preferably directed to some aspect of processing data at the reference address within the prefetch region, but not

10056247.012402

primarily directed to prefetching the prefetch block of data. Instead, the reference address is used with the other compile-time information to determine an address of the prefetch block of data.

5 To access the prefetch block of data, the reference address is first compared with the compile-time information to determine whether the reference address falls within the prefetch region of memory. The compile-time information is preferably obtained during compilation of all the program instructions which indicates the location of the bounds of the prefetch region, a size of a prefetch block of data, and an offset distance to a prefetch block from a reference address. However, the
10 the current reference address falls within the prefetch region, a specific address of the prefetch block is determined, based on the offset from the reference address. The prefetch block of data is then obtained from memory and communicated to a cache, so that the prefetched block of data is available for use by a processor.

15 The invention may prefetch data from a one-dimensional prefetch region or a multi-dimensional prefetch region, depending on the detail provided by the compile-time information. A one-dimensional prefetch region simply comprises a continuous segment of memory, and is easily defined by a base address and a size. For example, a one-dimensional prefetch region may store data representing an entire
20 image or an upper portion of an image. A two-dimensional prefetch region comprises an embedded segment of memory, the bounds of which may be defined by virtual horizontal and vertical dimensions. For example, a two-dimensional prefetch region may store data representing only a portion of an image, such as a rectangular portion disposed within the image. If only a portion of the image will be processed at a time,
25 it is beneficial to prefetch only data that correspond to the current portion of the image, rather than prefetching a continuous segment that includes excess data outside the desired portion of the image. Additional dimensions may be included to define the bounds of the prefetch region.

Similarly, the specific address of a prefetch block of data may be determined
30 in one dimension or multi dimensions. The specific address of a prefetch block of data in a one-dimensional prefetch region is determined by offsetting the reference address by a prefetch distance corresponding to a number of blocks that are the size of the prefetch block. The specific address of a prefetch block of data in a two-dimensional prefetch region requires more detailed offsetting in horizontal and
35 vertical directions, but is analogous to the one-dimensional case.

The prefetched block of data may be stored in a prefetch buffer or directly in a data area of the cache. Prior to performing a prefetch, the prefetch buffer, data area,

10056247 012402

or a write buffer may first be checked to determine whether the desired prefetch data is already available to the processor.

Another aspect of the invention is directed to a machine-readable medium storing machine instructions for performing the method described above.

5 A further aspect of the invention is directed to a system for program-directed prefetching of data. Such a system may be embodied as a media processor or as an on-chip unit in communication with the media processor. The primary components include a PDP controller, a cache, a function unit, and a memory. Preferably, the PDP controller comprises sets of region registers, each set of which stores
10 compile-time information defining a prefetch region. The PDP controller may control the prefetching process, or simply provide the compile-time information to a cache controller, which performs the prefetches. The cache also preferably includes a prefetch buffer for storing the prefetched data until the data are communicated to a data area of the cache for use by the function unit.

15 **Brief Description of the Drawing Figures**

The foregoing aspects and many of the attendant advantages of this invention will become more readily appreciated as the same becomes better understood by reference to the following detailed description, when taken in conjunction with the accompanying drawings, wherein:

20 FIGURE 1 illustrates a preferred embodiment of the present invention, incorporated into processor hardware;

FIGURE 2 illustrates a first data structure of compile-time information stored in hardware registers of the PDP controller used for one-dimensional prefetching;

25 FIGURE 3 illustrates a one-dimensional prefetch region in main memory from which data are loaded into cache;

FIGURE 4 is a flow diagram of logic for prefetching data from the main memory;

FIGURE 5 illustrates how data are accessed in row-major order for two sets of image blocks during an image transpose function;

30 FIGURE 6 illustrates a second data structure of compile-time information stored in hardware registers of the PDP controller used for two-dimensional prefetching; and

FIGURE 7 illustrates a two-dimensional prefetch region in main memory from which data are loaded into cache.

Description of the Preferred Embodiment

Description of System for Implementing the Present Invention

FIGURE 1 illustrates a preferred embodiment of the present invention, incorporated into processor hardware, such as a set-top box for video processing, graphics processing, gaming, or other media processing system. Such systems preferably include a two-issue, very long instruction word (VLIW) processor 10. Processor 10 includes a register file 12, which is in communication with a 256-bit partitioned function unit (PFU) 14 and a 32-bit scalar function unit (SFU) 16. The SFU has 32 32-bit registers and the PFU has 64 256-bit registers. Memory reference and control-flow instructions can only be executed on the SFU.

In communication with SFU 16 is a PDP controller 20 for performing prefetches and/or providing compile-time information for prefetches to be performed by another unit of the architecture. PDP controller 20 includes region register sets 22a through 22d. Each region register set includes a plurality of registers for storing the compile-time information that defines a prefetch region.

PDP controller 20 and SFU 16 are in communication with a cache 30 through a cache controller 32. Cache 30 preferably includes a 32-Kbyte, 4-way set-associative instruction cache area 34 that has a 32-byte cache line size. Cache 30 also preferably includes an 8-Kbyte, 4-way set-associative data cache area 35 that also uses a 32-byte cache line size. Data cache area 35 is preferably a blocking cache with a 64-cycle minimum cache miss delay. Data cache area 35 also preferably uses a least recently used (LRU) replacement policy, whereby the LRU lines will be replaced when more space is needed for new data. Further, for data cache area 35, cache 30 preferably uses a write-allocate policy, except for 256-bit register stores, where no data must be loaded. Cache 30 also preferably includes a tag list 36 for accessing data within cache 30. Transfers to and from instruction cache area 34, data cache area 35, and tag list 36 are managed by cache controller 32.

Also in communication with cache controller 32 is a prefetch buffer 38. Preferably, prefetch buffer 38 has a buffer size of 16 Kbytes and is organized as a LRU read cache. Prefetched data are stored in prefetch buffer 38, then copied (or moved) to individual cache lines of data cache area 35 when the prefetched data are referenced by a load or store instruction directed to primary processing of the previously prefetched data. Sixteen kilobyte (16-Kbyte) prefetch buffer 38 is relatively large compared to 8-Kbyte data cache area 35, because the ability to buffer significant amounts of prefetched data is more important in media processing than the ability to reaccess data quickly. In other words, because media processing applications typically lack temporal locality, a large cache is less important than a

large buffer. It is contemplated that prefetch buffer 38 could be incorporated into PDP 20, that PDP 20 could be incorporated into cache 30, but other configurations of these devices can alternatively be employed.

5 Balancing the on-chip memory requirements between data cache area 35 and prefetch buffer 38 can be difficult. For functions conducive to spatial locality, data cache area 35 may be of little importance. For example, in frame averaging there is no reuse of data. However, in other functions, such as two-dimensional convolution, there is significant data reuse and the data cache is important for reducing the main memory bandwidth requirements. To address this problem for a wide range of
10 functions, an alternative embodiment unifies prefetch buffer 38 and data cache area 35. In this embodiment, prefetch controller 20 stores prefetched data directly in data cache area 35.

15 Unfortunately, prefetches can evict useful data from the cache. Furthermore, pressure on access ports of data cache area 35 may increase, because it is possible that cache accesses and writing of prefetched data could occur simultaneously. To address this problem, another alternative embodiment uses a dual-ported data cache. This embodiment may reduce the space savings obtained from unifying data cache area 35 and prefetch buffer 38, depending on target applications, available chip design, and very large scale integration (VLSI) technologies.

20 A write buffer 39 that helps to issue writes in bursts to a main memory 40 is in communication with cache controller 32. Write buffer 39 does not begin writing back until after 96 cache lines have been stored (i.e., hi-level = 96). At that point, cache controller 32 completely empties write buffer 39 (i.e., lo-level = 0). Even though cache misses cannot be serviced while write buffer 39 is being written back,
25 this technique improves overall execution time, because writes that are intermixed with read accesses typically incur a page miss on each write.

Cache controller 32 is also in communication with main memory 40 that stores data and machine instructions. Main memory 40 is preferably a synchronous dynamic random access memory (SDRAM), such as a PC800 Direct RAMBUS™
30 main memory. Main memory 40 preferably has at least a peak transfer rate of 64 bits of data per processor cycle. Peak main memory bandwidth is preferably obtained, for example, by employing at least a 400 MHz processor clock and two 16-bit memory channels, such as RAMBUS™ channels.

Prefetching in One Dimension

35 In one preferred embodiment, the compile-time information defines the extent of a prefetch region within the main memory and also defines basic information about how to prefetch data. Preferably, up to four prefetch regions are defined. FIGURE 2

illustrates a first data structure of compile-time information stored in hardware registers of the PDP controller used for prefetching. For example, a first set of region registers 22a includes a base address 50a, which is the starting address within main memory of a first prefetch region. A size 52a indicates a number of bytes within
5 which image, video, or graphics data are stored. For example, size 52a may be 250 Kbytes corresponding to the storage size of a first image. Base address 50a and size 52a define the starting and ending limits of the first prefetch region, respectively.

A prefetch size (PF_SIZE) 54a defines a block size of prefetch data and depends on the image function being performed. Preferably prefetch size 54a
10 corresponds to a page size of dynamic random access memory (DRAM) and is preferably 4 Kbytes or smaller. Accordingly, prefetches will occur in blocks of data that are the size defined by PF_SIZE 54a.

A prefetch distance (PF_DIST) 56a indicates a number of blocks of PF_SIZE 54a between a reference address and a desired prefetch block. An
15 instruction, such as a load instruction, is executed by the processor primarily to process data from the reference address, which is not that of data to be currently prefetched. However, if the reference address falls within the prefetch region, it is safe to assume that other data in the prefetch region will soon be needed for processing. Therefore, other data in the prefetch region can be prefetched, so that the
20 other data will be available to the processor when needed. Effectively, the reference address of an instruction to process similar previous data indirectly provides a hint to prefetch subsequent data in the prefetch region, and indicates where to prefetch that subsequent data. PF_DIST 56a identifies a number of blocks of size, PF_SIZE 54a, beyond the reference address, where the desired prefetch block is located. Thus,
25 PF_DIST 56a indicates an offset number of blocks beyond the reference address in memory where data are to be prefetched and loaded into the cache. For example, if PF_DIST 56a is set to five (5), a prefetch will be issued for data at the fifth block following the reference address.

A mode 58a identifies the type of loading to accomplish. Preferably,
30 mode 58a indicates "preload" most of the time; i.e., that data are to be preloaded from main memory into the cache. The mode may also identify whether prefetching is to be done in one dimension or two dimensions, as discussed below. As indicated above, the information shown in FIGURE 2 is stored in hardware registers and can be modified by special assembly language instructions. The special assembly language
35 instructions to configure the hardware registers also represent hints included in the programmed instructions or come directly from the compiler. Typically, the compiler or programmer will set these registers before entering a tight loop of a function to be

processed. It is contemplated that the compiler could use profiling to identify memory regions that are likely to benefit from prefetching.

FIGURE 3 illustrates a prefetch region 60 in main memory from which data are loaded into cache. As indicated above, the hardware registers of FIGURE 2 identify the characteristics of prefetch region 60 in FIGURE 3, and are used to initiate prefetches from prefetch region 60. Those skilled in the art will recognize that the base address is only logically aligned with a logical edge of memory, not physically aligned with any physical aspect of memory. When a reference address of a load instruction (REF_ADDR) 64 falls within prefetch region 60, a prefetch block 62 is computed. The size of prefetch block 62 is defined by the prefetch size, such as PF_SIZE 54a, which must be a power of two. The distance from the reference address of the load instruction to prefetch block 62 is approximately equal to a product of the prefetch distance and the prefetch size (e.g., PF_DIST 56a*PF_SIZE 54a). The exact address of the prefetch block is a sum of the reference address and approximate distance to the load instruction, less the modulus of the reference address and the prefetch size (i.e., $\text{REF_ADDR } 64 + (\text{PF_DIST } 56a * \text{PF_SIZE } 54a) - (\text{REF_ADDR } 64 \% \text{PF_SIZE } 54a)$). The prefetch block is aligned to a grid with each cell equal to the size of the prefetch size (i.e., PF_SIZE 54a). A prefetch block is loaded from main memory if and only if the prefetch block is contained within the prefetch region, and the prefetch block does not already exist in the prefetch buffer, write buffer, or the data cache.

FIGURE 4 is a flow diagram of the logic for prefetching data from the main memory as needed. The flow diagram shows the steps for obtaining a block of data from one prefetch region defined by a set of registers, such as registers 22a. However, the same logic applies to obtaining a block of data from each other prefetch region defined by each other set of registers, such as registers 22b, 22c, and 22d. At a decision step 70, the prefetch controller evaluates the base address (e.g., base address 50a) and the size (e.g., size 52a) of each prefetch region against the reference address of a load or store instruction, to determine whether the reference address falls within a prefetch region. If the reference address does not fall within a prefetch region, the processor must access the data from the main memory without prefetching. However, if the reference address does fall within a prefetch region, the prefetch controller computes the address of the prefetch block at a step 72, as described above.

At a decision step 74, the prefetch controller determines through the cache controller whether the prefetch block is already stored in the prefetch buffer. If so, the prefetch controller instructs the cache controller, at a step 76, to move (or copy)

the prefetch block from the prefetch buffer to the data cache area for access by the processor upon execution of the load or store instruction.

If the prefetch block is not stored in the prefetch buffer, the prefetch controller determines, at a decision step 78, whether the prefetch block is already stored in the write buffer. If so, the prefetch controller instructs the cache controller, at a step 80, to copy (or move) the prefetch block from the write buffer to the data cache area.

If the prefetch block is not stored in the write buffer, the prefetch controller determines, at a decision step 82, whether the prefetch block is already stored in the data cache area. If the prefetch block is stored in the data cache area, control returns from the prefetch controller.

If the prefetch block is not stored in the data cache area, the prefetch controller accesses the main memory and copies the prefetch block to the prefetch buffer, at a step 84. The prefetch controller then instructs the cache controller, at a step 86, to copy the prefetch block to the prefetch buffer to the data cache area.

Simulation Results

Three separate on-chip memory models were simulated to evaluate the embodiment described above. The first on-chip memory model is based on the prior art and is referred to as a DMA model. The DMA model simulates an advanced DMA controller that transfers data between the RAMBUS main memory and a 32-Kbyte on-chip scratchpad memory. This 32-Kbyte on-chip scratchpad memory can sustain a bandwidth of 256 bits per cycle. Functions that use this on-chip memory model can use double buffering in the on-chip memory.

The second on-chip memory model is also based on the prior art, and is referred to as a data cache only model. The data cache only model implements the 8-Kbyte, 4-way set-associative data cache described above without the PDP controller and without the prefetch buffer. However, the data cache only model does include the write buffer. Peak transfer rates from the main memory to the cache memory, and from the cache memory to the functional units, are identical to the DMA model with the DMA controller.

The third on-chip memory model represents the embodiment of the invention described above, including the PDP controller and prefetch buffer. For simulation purposes, two sub-models were tested. Sub-models 3a and 3b correspond to two different prefetch buffer sizes. Sub-model 3a has a prefetch buffer size of 16 Kbytes, so it is referred to as a PDP-16K model. Sub-model 3b has a prefetch buffer size of 32 Kbytes and is referred to as a PDP-32K model. The larger buffer size of the PDP-32K model is useful for certain media functions that have high spatial locality, such as a transpose function. For such functions,

the PDP-32K model was used to illustrate how a slightly different prefetching hardware and scheme affects performance characteristics.

TABLE 1 summarizes the simulation parameters of the three models. Note that the instruction cache is found in all three models, whereas the data cache is found only in the latter two memory models and prefetching is supported only in the third memory model.

TABLE 1: SIMULATION PARAMETERS OF THREE MODELS

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
Instruction Cache	Size: 32 Kbytes Line size: 32 bytes Associativity: 4-way			
Scratchpad Memory	Size: 32 Kbytes 64-cycle minimum delay to main memory	None	None	
Data Cache	None	Size: 8 Kbytes Line size: 32 bytes Associativity: 4-way Write Policy: writeback with 4-Kbyte write buffer Write buffer writeback levels: hi=96, lo=0 Write miss policy: write allocate for scalar stores No write allocate for vector stores Replacement policy: least recently used 64-cycle minimum cache miss delay		
Prefetch Buffer	None	None	Sub-Model 3a (PDP-16K)	Sub-Model 3b (PDP-32K)
			Size: 16 Kbytes	Size: 32 Kbytes
			Line size 32 bytes Prefetch address buffer size: 10 addresses total Prefetch regions: 4 3-cycle hit delay	

Simulations were conducted to evaluate three main performance characteristics; overall execution time, memory bandwidth, and memory latency. For each characteristic, the PDP models (PDP-16K and PDP-32K) were compared with the two prior art memory models. Four functions were simulated with each memory model; frame average, binary dilate (using a 5 x 5 kernel), two-dimensional convolution (using a 3 x 3 kernel), and transpose. For each function, TABLE 2 lists the compile-time information stored in the hardware registers of the PDP models.

TABLE 2: COMPILE-TIME INFORMATION

	Frame Average		Binary Dilate	Two-Dimensional Convolution	Image Transpose	
	Region 1	Region 2			(PDP-16K)	(PDP-32K)
	Region 1	Region 2	Region 1	Region 1	Region 1	Region 1
BASE	Base address of source image 1	Base address of source image 2	Base address of source image	Base address of source image	Base address of source image	Base address of source image
SIZE	Size of source image 1	Size of source image 2	Size of source image	Size of source image	Size of source image	Size of source image
PF_SIZE	4096 bytes	4096 bytes	4096 bytes	4096 bytes	16384 bytes	4096 bytes
PF_DIST	1 block	1 block	1 block	1 block	0 blocks	4 blocks
MODE	w/preload	w/preload	w/preload	w/preload	w/preload	w/preload

The specified preload mode means that the first reference to a prefetch region issues a prefetch for all data from the reference address through the end of the prefetch block, rather than prefetching only the individual prefetch block. Prefetching all the data at once reduces any penalty due to cold misses.

TABLE 3 lists the total execution time in cycles for all four functions using each model. In comparison to the DMA model (model 1), the performance of model 2 is generally very poor, due to the low memory bandwidth and inability to hide the memory latency. Increasing the data cache size to 32 Kbytes for model 2 resulted in equivalent execution times. No improvement in the execution time occurred for reasons related to data reuse. Functions such as the frame average and image transpose functions use each piece of data only once. Thus, the processor cannot utilize the data multiple times from cache. Therefore, increasing the data cache size does not improve execution time. Other functions, such as the two-dimensional convolution function, only process small blocks of the frame data at a time in a tight loop. Thus, only small blocks of data are reused at a time. Again, the processor cannot repetitively use the same data from the cache, so increasing the data cache size does not improve execution time.

In contrast, the program-directed prefetching model at least maintains the execution time at a level comparable to that of the DMA-based model, but eliminates the detailed programming required for the DMA approach. Note that the first three functions were not performed for the PDP-32K model, but would produce the same results obtained for the PDP-16K model.

TABLE 3: EXECUTION TIME (IN CYCLES)

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
			(PDP-16K)	(PDP-32K)
Frame Average	114k	1050k	112k	n.a.
Binary Dilate	115k	201k	113k	n.a.
2D Convolution	166k	699k	184k	n.a.
Image Transpose	104k	568k	122k	78k

TABLE 4 shows the effect of DRAM page accesses in the data transfer. It is possible to estimate a peak bandwidth of DRAM memory based on a clock rate and data width. However, the measured memory bandwidth is lower than the peak bandwidth. The measured memory bandwidth also depends on the ordering of addresses and timing of requests. Generally, ordering the addresses to be consecutive, so that multiple requests can hit the same page at a time, will achieve a higher bandwidth. The timing of requests can affect the bandwidth as well because some DRAM controllers (such as the one used in this simulation) will automatically close a DRAM page after some idle time has lapsed.

TABLE 4: MEMORY BANDWIDTH (MBYTES/SECOND)

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
			(PDP-16K)	(PDP-32K)
Frame Average	2980	1340	3070	n.a.
Binary Dilate	2720	1410	2750	n.a.
2D Convolution	2980	1540	3040	n.a.
Image Transpose	2620	1540	2980	3070

The active bandwidth shown in TABLE 4 is the average data transfer rate obtained during active use of RAMBUS memory (for simulation purposes, the RAMBUS memory was considered to be actively used when its command queue contained outstanding read or write requests). The average data transfer rate by itself was not used, because it is not a good indicator of how efficiently the memory bandwidth is utilized. In particular, a high cache-hit ratio or a compute-bound function can lead to long idle periods in the memory system. These idle periods reduce the average data transfer rate, but idle periods are not necessarily an indicator of poor memory utilization. Memory idle periods in simulations varied from between 7 percent and 91 percent, as shown in TABLE 5.

TABLE 5: MEMORY IDLE TIME (PERCENT OF EXECUTION TIME)

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
			(PDP-16K)	(PDP-32K)
Frame Average	7	78	8	n.a.
Binary Dilate	91	88	89	n.a.
2D Convolution	57	80	61	n.a.
Image Transpose	23	76	42	12

As can be seen from TABLE 4, the DMA-based model and the program-directed prefetch model achieve an active bandwidth very nearly the same, but almost twice that of the data cache only model. The reason for the similarity between the results for the DMA model and the PDP model is that they both transfer relatively large blocks of data containing sequences of consecutive addresses. Because the data cache only model is a blocking cache, it will always incur a page miss (i.e., the DRAM page will be automatically closed when the DRAM page is idle).

The largest difference in bandwidth between the DMA-based model and the program-directed prefetch model exists in the transpose function. The active bandwidth of the PDP-32K model is 17% higher than that of the DMA-based model. This difference occurs because the DMA program for transpose was programmed to transfer 32 x 32-byte sub-blocks from 512 x 512-byte input data, resulting in accesses across four DRAM pages for a single sub-block (each DRAM page has a size of 4 Kbytes). The PDP-32K model instead buffers whole DRAM pages in the prefetch buffer, achieving a better active bandwidth. Those skilled in the art will recognize that with the necessary on-chip memory space, the above improvement could also be achieved by the DMA program as well. The PDP-32K model achieves a higher active bandwidth, because the PDP-32K model has a larger prefetch buffer than the PDP-16K model, which is unable to store as many DRAM pages at a time in the smaller 16 Kbyte prefetch buffer.

TABLE 6 lists memory latencies for a memory store instruction, measured in stall cycles per memory store instruction. This simulation is not applicable to the DMA model. To measure memory latency for the cache-based models, the total number of stall cycles due to memory instructions were divided by the total number of memory references. The numbers were separated between load and store instructions.

TABLE 6: STORE LATENCY (STALL CYCLES PER STORE INSTRUCTION)

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
			(PDP-16K)	(PDP-32K)
Frame Average	n.a.	2.06	2.09	n.a.
Binary Dilate	n.a.	2.67	2.90	n.a.
2D Convolution	n.a.	2.08	2.05	n.a.
Image Transpose	n.a.	2.01	2.03	2.47

There was little difference between the data cache only model (model 2) and the program-directed prefetch model (model 3). Sometimes the program-directed prefetch model incurred a slightly higher latency, which can happen when the write buffer fills while a long prefetch is in progress. The memory instruction that causes the write buffer to be filled has to stall the main processor until the prefetch completes. Most store instructions incur cache misses because store instructions are almost always used exclusively for storing the result of the computation to a new destination location (intermediate results are always kept in registers). The latency is relatively low even for cache misses, because 256-bit register stores do not need to allocate cache lines.

TABLE 7 lists memory latencies for a memory load instruction, also measured in stall cycles per memory load instruction.

TABLE 7: LOAD LATENCY (STALL CYCLES PER LOAD INSTRUCTION)

	Model 1 (DMA)	Model 2 (Data Cache Only)	Model 3 (PDP with PF Buffer)	
			(PDP-16K)	(PDP-32K)
Frame Average	n.a.	60.70	3.22	n.a.
Binary Dilate	n.a.	2.91	0.116	n.a.
2D Convolution	n.a.	12.70	0.432	n.a.
Image Transpose	n.a.	63.10	8.58	2.35

Two different types of functions can be recognized here. Frame average and image transpose functions have nearly zero cache hits. For the data cache only model (model 2), load instructions typically have a latency equal to the memory latency, which is roughly 60 cycles, because a blocking data cache is used. With the program-directed prefetch model (model 3), load instructions incur a prefetch hit that has a minimum latency of two cycles. The prefetch hit latency can be larger than two cycles when there is a late prefetch (a memory access to the cache line that is being prefetched) or when cache replacements fill the write buffer. Late prefetches happen

frequently when a computation on the fetched data is simple, as is the case in frame average and image transpose functions.

The other type of functions, including binary dilate, and two-dimensional convolution, reuse data. This reuse explains why the average memory read latency is so much lower than with frame average and image transposition functions. Nevertheless, the ratio of instruction latency cycles between the data cache only model and the program-directed prefetch model remains roughly the same (about 25:1 to 30:1).

Prefetching in Two Dimensions

The compile-time parameters discussed above that are stored in the hardware registers of the PDP controller provides a data structure for prefetching in one dimension. One-dimensional prefetching corresponds to accessing data in a single row of memory. The only way to access the next row of memory is to wrap around the end from the previous row. Such an access method is referred to as row-major order. For example, FIGURE 5 illustrates how data are accessed in row-major order for two sets of image blocks during an image transpose function. Each set of blocks, A and B, comprises 256 blocks that are each 32 x 32-bytes (i.e., 32 bytes by 32 bytes for a total of 1024 bytes per block). To perform the image transpose function on one portion of the image, one set of blocks are accessed in row-major order. The number inside each block represents the order in which each block of a set is accessed for the transpose function.

However, each row of blocks requires multiple rows of memory to store the portions of the image stored in each block. With reference to FIGURE 5, each row of blocks of the image requires 32 rows of memory, because the height of a block is 32 bytes. Moreover, sets A and B of FIGURE 5 illustrate that only a portion of an overall image might be transposed at a time. Correspondingly, only a portion of the data in memory may need to be prefetched at a time. For example, if the blocks comprising set A were to be transposed, none of the blocks of set B would be needed. However, using row-major order to access the data of set A would require accessing data all the way to the end of a memory row that includes data for set B, before wrapping back around to the next memory row of data for set A. The length of an entire image is generally referred to as its pitch. For example, the pitch across both sets A and B is 1024 bytes. The length of a desired portion of an image is generally referred to as its width. For example, set A has a width of 512 bytes. Note that the byte values above are much smaller than those suggested by FIGURE 3, where the pitch and width both equal 16,384 bytes (i.e., 4096 bytes per prefetch block times 4 blocks per row).

10056247 "012402

The prior art DMA model discussed above enables a programmer to transfer individual blocks of data from within a desired memory region (e.g., within a single DRAM page) without tying up the CPU, because the DMA model can transfer individual blocks in the order requested by the image function being performed. However, the DMA model requires the programmer to identify the detailed memory locations to be transferred. Also, unless all the desired data falls within a single DRAM page, multiple DRAM pages must be accessed, which introduces inefficiencies. For example, the prior art DMA model can transfer data for a single block of set A in FIGURE 5 to use in transposing that image block. However, an entire block does not fall within a single DRAM page. Assuming a DRAM page size of 4,096 bytes, each DMA access of a DRAM page would access data for four horizontal rows of image blocks 1A through 16B (i.e., 4,096 bytes divided by 1,024 bytes per memory row of 32 total image blocks across sets A and B, equals 4 memory rows). Because the image transpose function requests an entire block, yet a entire block is not contained in a single DRAM page, the transfer of only a portion of a block from each accessed DRAM page results in a page miss. To access the remaining 28 rows to complete a single block, seven more DRAM pages would have to be accessed, each comprising four horizontal memory rows. Therefore, to access one complete 32 x 32-byte block, a total of eight DRAM pages must be accessed, resulting in eight page misses.

Rather than having the DMA controller predetermine the portions of a DRAM page to transfer to cache, the one-dimensional PDP embodiments discussed above can prefetch a whole DRAM page at a time, place the prefetched data into the prefetch buffer, and then allow the cache controller to obtain the portion needed. With a large prefetch buffer, all the DRAM pages required to cover an entire image block could be prefetched to the prefetch buffer. However, the prefetch buffer would have to be large enough to hold data that is currently being accessed by the cache controller for processing, and the next set of prefetched data.

The one-dimensional PDP-32K model described above could be used to prefetch data for two rows of 16 image blocks of one set of image blocks, if the pitch and width were equal at 512 bytes (i.e., if the entire image comprised only set A blocks stored in memory). Assuming a prefetch size of 4,096 bytes set equal to the DRAM page size of 4,096 bytes, the 32 Kbyte prefetch buffer of the PDP-32K model could hold data for 32 whole image blocks (i.e., 1024 bytes per block times 32 blocks equals 32 Kbytes). A 32 Kbyte prefetch buffer would enable the processor to reference the data for entire blocks 1A through 16A, while blocks 17A through 32A are prefetched. Thus, for a small image and/or large enough prefetch buffer, the

one-dimensional PDP-32K model provides higher performance for the transpose function than the DMA model and the PDP-16K model (as is shown in TABLE 3).

However, when the horizontal dimension of the image is large (such as when the image pitch is different than the width for both sets A and B), or when the prefetch buffer size is small (such as 16 Kbytes), the one-dimensional PDP-32K model may not be applicable. For example, if the transpose function is to be performed on set A image blocks of FIGURE 5 and data for both sets A and B are stored in memory, data from the prefetch buffer would replace data in the data area of the cache before the data in the data area of the cache are referenced by the processor. This premature replacement would occur because there is insufficient space in the prefetch buffer to hold all the excess prefetched data of set B image blocks. When the processor starts referencing the data of block 1A (that were previously prefetched to the prefetch buffer), the PDP controller will instruct the cache controller to start prefetching data for block 17A. However, because the data of block 1A is the oldest data in the prefetch buffer and the prefetch buffer is full of data from blocks 1A through 16B, the cache controller will start to replace the data of block 1A with the data of block 17A. This replacement will occur just when the processor needs the data from block 1A.

In these circumstances, it is preferable to avoid all the excess data beyond the desired width, and instead skip the excess data by prefetching with vertical capability, thereby prefetching the data in the flow direction of only the desired transpose data (shown in FIGURE 5), as is done by the DMA model. To support prefetching in two dimensions, a second preferred embodiment is provided. Specifically, a second data structure of compile-time information is stored in a new set of hardware registers, and a more sophisticated computation is performed to obtain a desired prefetch block.

FIGURE 6 illustrates a second data structure of compile-time information stored in hardware registers of the PDP controller used for prefetching. As with the one-dimensional embodiment above, multiple sets of region registers 100a, 100b, etc. specify prefetch regions in memory containing data to be prefetched. Also like the one-dimensional embodiments discussed above, a set of region registers 100a includes a base address 102a, which is the starting address within main memory of a two-dimensional prefetch region. However, region registers 100a provide more detailed information to define an embedded two-dimensional prefetch region rather than a continuous one-dimensional prefetch region size.

For example, region registers 100a include a pitch 104a, a width 106a, and a height 108a. As described above with respect to FIGURE 5, pitch 104a of FIGURE 6 may correspond to a total horizontal length of an image, which can be represented by

a number of blocks in a virtual row of memory. Similarly, width 106a may correspond to a horizontal length of only a desired portion of the total image, and can also be represented by a number of blocks in a virtual row of memory. The width is less than, or equal to, the pitch. Height 108a may correspond to the second dimensional size of the desired portion of the image, and may be represented by a number of vertical blocks or number of virtual rows in memory. By providing separate fields for the pitch, width, and height, a two-dimensional prefetch region can be defined. Defining a two-dimensional prefetch region makes it possible, for example, to restrict prefetching to a vertical strip of an image, rather than having to wrap around unneeded data.

A prefetch width (PF_WIDTH) 110a is similar to the prefetch size (PF_SIZE) of the one-dimensional embodiment, and depends on the image function being performed. For example, to perform the image transpose function described with respect to FIGURE 5, the prefetch width would preferably be set to 32 bytes, corresponding to the width of a single block. Similarly, a prefetch height (PF_HEIGHT) 112a in FIGURE 6 is set to a number of bytes that defines a vertical dimension of a prefetch block. For example, to perform the image transpose function described with respect to FIGURE 5, the prefetch height would also preferably be set to 32 bytes, corresponding to the height of a single block. Thus, the data for a whole image block could be prefetched directly without prefetching excess unneeded data.

To identify the block in the two-dimensional prefetch region that is to be obtained, a slightly different offsetting method is used for a two-dimensional prefetch region. With a one-dimensional prefetch region, a prefetch distance, PF_DIST, can be used as a sequential offset directly from a reference address provided in a load instruction. However, a two-dimensional prefetch region is embedded within memory, rather than simply defining a continuous sequential portion of memory. Thus, an offset cannot be taken directly from the reference address. Instead, an offset is taken from a grid base, which is the first byte of a block that the reference address falls within. From the grid base, a prefetch width distance (PF_WIDTH_DIST) 114a and a prefetch height distance (PF_HEIGHT_DIST) 116a are used as offset coordinates. Prefetch width distance 114a indicates a number of blocks of a width PF_WIDTH in a horizontal direction to a desired prefetch block from the grid base. Similarly, prefetch height distance 116a indicates a number of blocks of a height PF_HEIGHT in a vertical direction to a desired prefetch block from the grid base. As with the one-dimensional prefetcher, if the desired block falls outside the prefetch region, the desired block will not be prefetched, and must be obtained through normal memory access methods.

As with the one-dimensional embodiment, a mode 118a identifies the type of loading to accomplish. Preferably, mode 118a will indicate "preload" most of the time, indicating that data are to be preloaded from main memory into the cache.

To further explain two-dimensional prefetching, FIGURE 7 illustrates a two-dimensional prefetch region 130 in main memory from which data are loaded into the cache. As indicated above, the hardware registers of FIGURE 6 identify the characteristics of prefetch region 130 in FIGURE 7 and are used to initiate prefetches from prefetch region 130. Also, as above, those skilled in the art will recognize that the base address is only logically aligned with a logical edge of memory, not aligned with any physical edge of the memory. Thus, the prefetch region may fall anywhere within the memory space.

A location of a desired prefetch block 132 is computed from the parameters in the hardware registers. Although the calculation may be performed directly, it is broken into two steps for illustrative purposes. When a reference address of a load instruction (REF_ADDR) falls within prefetch region 130, a grid base (GRID_BASE) is first determined. As indicated above, the grid address corresponds to the first byte of a block that the reference address falls within. The grid address is computed with the following expression:

$$\begin{aligned} \text{REF_ADDR} - (\text{REF_ADDR} \% (\text{PF_HEIGHT} * \text{PITCH})) \\ + (\text{REF_ADDR} \% \text{PITCH}) - (\text{REF_ADDR} \% \text{PF_WIDTH}). \end{aligned}$$

The grid base can be computed in hardware by a sequence of additions and bit shifting if the pitch, prefetch width (PF_WIDTH), and prefetch height (PF_HEIGHT) are powers of two.

The distance from the grid base to prefetch block 132 is computed with the following expression:

$$(\text{PF_HEIGHT_DIST} * \text{PF_HEIGHT} * \text{PITCH}) + (\text{PF_WIDTH_DIST} * \text{PF_WIDTH})$$

Note that if the dimensions of the cells of the grid shown in FIGURE 7 are powers of two, the multiplications reduce to shift operations. Also, the two-dimensional prefetching technique described above can be used for one-dimensional prefetching by setting the prefetch height (PF_HEIGHT) to one (1) and the prefetch height distance (PF_HEIGHT_DIST) to zero (0), while using a prefetch region with a height of one (1) and a pitch equal to the width. The two-dimensional calculations above are performed at step 72 of FIGURE 4, in an analogous fashion to the one-dimensional calculations at this step.

Although the present invention has been described in connection with the preferred form of practicing it, those of ordinary skill in the art will understand that

many modifications can be made thereto within the scope of the claims that follow. For example, as indicated above, those skilled in the art will recognize that the invention could be extended to prefetch data from a three-dimensional prefetch region, or any other multi-dimensional prefetch region, provided the compile-time information identifies the bounds of the prefetch region. Further, the invention may prefetch data that are stored at an address occurring before the reference address, or in another order rather than simply being disposed after the reference address. Prior or random prefetching may be beneficial for data that are not stored in a bounded prefetch region. Even for data that are stored in a bounded prefetch region, it may be valuable to prefetch data stored before the reference address, such as for repeated prefetching of data in a processing loop. If it is known that a looping process will continue to repeatedly access the same data, or updated data, that are stored in the prefetch region, but which are too large to all be maintained in the cache, it may be beneficial to prefetch the data that are stored before the reference address, rather than wait until the loop starts again at the beginning of the prefetch region. Alternatively, it may be beneficial to prefetch data that are stored before the reference address, rather than requiring a determination that the offset from the reference address must wrap around to the beginning of the prefetch region. For example, a Gaussian-type prefetch from the middle of the prefetch region may be incorporated. Accordingly, it is not intended that the scope of the present invention in any way be limited by the above description, but instead be determined entirely by reference to the claims that follow.
